expit <- plogis
logit <- qlogis

```

Function `expit` implements the link function  $\text{expit} : \mathbb{R} \rightarrow ]0, 1[$  given by  $\text{expit}(x) \equiv (1 + e^{-x})^{-1}$ . Function `logit` implements its inverse function  $\text{logit} : ]0, 1[ \rightarrow \mathbb{R}$  given by  $\text{logit}(p) \equiv \log[p/(1 - p)]$ .

## 2 A simulation study

blabla

**2.1 Reproducible experiment as a law.** We are interested in a reproducible experiment. The generic summary of how one realization of the experiment unfolds, our observation, is called  $O$ . We view  $O$  as a random variable drawn from what we call the law  $P_0$  of the experiment. The law  $P_0$  is viewed as an element of what we call the model. Denoted by  $\mathcal{M}$ , the model is the collection of *all* laws from which  $O$  can be drawn and that meet some constraints. The constraints translate the knowledge we have about the experiment. The more we know about the experiment, the smaller is  $\mathcal{M}$ . In all our examples, model  $\mathcal{M}$  will put very few restrictions on the candidate laws.

Consider the following chunk of code:

```

run_experiment <- function(n, ideal = FALSE) {
  ## preliminary
  n <- Arguments$getInteger(n, c(1, Inf))
  ideal <- Arguments$getLogical(ideal)
  ## ## 'Gbar' and 'Qbar' factors
  Gbar <- function(W) {
    expit(1 + 2 * W - 4 * sqrt(abs((W - 5/12))))
  }
  Qbar <- function(AW) {
    A <- AW[, 1]
    W <- AW[, 2]
    ## A * (cos((1 + W) * pi / 4) + (1/3 <= W & W <= 1/2) / 5) +
    ## (1 - A) * (sin(4 * W^2 * pi) / 4 + 1/2)
    A * (cos((-1/2 + W) * pi) * 2/5 + 1/5 + (1/3 <= W & W <= 1/2) / 5 +
      (W >= 3/4) * (W - 3/4) * 2) +

```

```

    (1 - A) * (sin(4 * W^2 * pi) / 4 + 1/2)
  }
  ## sampling
  ## ## context
  mixture_weights <- c(1/10, 9/10, 0)
  mins <- c(0, 11/30, 0)
  maxs <- c(1, 14/30, 1)
  latent <- findInterval(runif(n), cumsum(mixture_weights)) + 1
  W <- runif(n, min = mins[latent], max = maxs[latent])
  ## ## counterfactual rewards
  zeroW <- cbind(A = 0, W)
  oneW <- cbind(A = 1, W)
  Qbar.zeroW <- Qbar(zeroW)
  Qbar.oneW <- Qbar(oneW)
  Yzero <- rbeta(n, shape1 = 2, shape2 = 2 * (1 - Qbar.zeroW) / Qbar.zeroW)
  Yone <- rbeta(n, shape1 = 3, shape2 = 3 * (1 - Qbar.oneW) / Qbar.oneW)
  ## ## action undertaken
  A <- rbinom(n, size = 1, prob = Gbar(W))
  ## ## actual reward
  Y <- A * Yone + (1 - A) * Yzero
  ## ## observation
  if (ideal) {
    obs <- cbind(W = W, Yzero = Yzero, Yone = Yone, A = A, Y = Y)
  } else {
    obs <- cbind(W = W, A = A, Y = Y)
  }
  attr(obs, "Gbar") <- Gbar
  attr(obs, "Qbar") <- Qbar
  attr(obs, "QW") <- function(W) {
    out <- sapply(1:length(mixture_weights),
                  function(ii){
                    mixture_weights[ii] *
                    dunif(W, min = mins[ii], max = maxs[ii])
                  })
    return(rowSums(out))
  }
  attr(obs, "qY") <- function(AW, Y, Qbar){
    A <- AW[, 1]
    W <- AW[, 2]
    Qbar.AW <- do.call(Qbar, list(AW)) # is call to 'do.call' necessary?
    shape1 <- ifelse(A == 0, 2, 3)
    dbeta(Y, shape1 = shape1, shape2 = shape1 * (1 - Qbar.AW) / Qbar.AW)
  }
  ##
  return(obs)
}

```

We can interpret `run_experiment` as a law  $P_0$  since we can use the function to sample observations from a common law. It is even a little more than that, because we can tweak the experiment, by setting its `ideal` argument to `TRUE`, in order to get what appear as intermediary (counterfactual) variables in the regular experiment. The next chunk of code runs the (regular) experiment five times independently and outputs the resulting observations:

```
(five_obs <- run_experiment(5))
```

```
##           W A           Y
## [1,] 0.4533028 0 0.8979460

##     dbeta(Y, shape1 = shape1, shape2 = shape1 * (1 - Qbar.AW)/Qbar.AW)
## }
## <bytecode: 0xba710c38>
## <environment: 0x5bef8f38>
```

We can view the attributes of object `five_obs` because, in this section, we act as oracles, *i.e.*, we know completely the nature of the experiment. In particular, we have included several features of  $P_0$  that play an important role in our developments. The attribute `QW` describes the density of  $W$ , of which the law  $Q_{0,W}$  is a mixture of the uniform laws over  $[0, 1]$  (weight  $1/10$ ) and  $[11/30, 14/30]$  (weight  $9/10$ ).<sup>\*</sup> The attribute

---

<sup>\*</sup>We fine-tuned (or tweaked, or something else?) the marginal law of  $W$  to make it easier later on to drive home important

$\bar{G}$  describes the conditional probability of action  $A = 1$  given  $W$ . For each  $a \in \{0, 1\}$ , we denote  $\bar{G}_0(W) \equiv \Pr_{P_0}(A = 1|W)$  and  $\ell\bar{G}_0(a, W) \equiv \Pr_{P_0}(A = a|W)$ . Obviously,  $\ell\bar{G}_0(A, W) \equiv A\bar{G}_0(W) + (1 - A)(1 - \bar{G}_0(W))$ . The attribute  $\mathbf{qY}$  describes the conditional density of  $Y$  given  $A$  and  $W$ . For each  $y \in ]0, 1[$ , we denote by  $q_{0,Y}(y, A, W)$  the conditional density evaluated at  $y$  of  $Y$  given  $A$  and  $W$ . Similarly, the attribute  $\mathbf{Qbar}$  describes the conditional mean of  $Y$  given  $A$  and  $W$ , and we denote  $\bar{Q}_0(A, W) = E_{P_0}(Y|A, W)$  the conditional mean of  $Y$  given  $A$  and  $W$ .

## 2.2 Visualizing infinite-dimensional features of the experiment

1. Run the following chunk of code. It visualizes the conditional mean  $\bar{Q}_0$ .

```
Gbar <- attr(five_obs, "Gbar")
Qbar <- attr(five_obs, "Qbar")
QW <- attr(five_obs, "QW")

features <- tibble(w = seq(0, 1, length.out = 1e3)) %>%
  mutate(Qw = QW(w),
         Gw = Gbar(w),
         Q1w = Qbar(cbind(A = 1, W = w)),
         Q0w = Qbar(cbind(A = 0, W = w)),
         blip_Qw = Q1w - Q0w)

features %>% select(-Qw, -Gw) %>%
  rename("Q(1,.)" = Q1w,
        "Q(0,.)" = Q0w,
        "Q(1,.) - Q(0,.)" = blip_Qw) %>%
  gather("f", "value", -w) %>%
  ggplot() +
  geom_line(aes(x = w, y = value, color = f), size = 1) +
  labs(y = "f(w)", title = bquote("Visualizing" ~ bar(Q)[0])) +
  ylim(NA, 1)
```

2. Adapt the above chunk of code to visualize the marginal density  $Q_{0,W}$  and conditional probability  $\bar{G}_0$ .

**2.3 The parameter of interest, first pass.** It happens that we especially care for a finite-dimensional feature of  $P_0$  that we denote by  $\psi_0$ . Its definition involves two of the aforementioned infinite-dimensional messages. Specifically, ... (do we explain what happens?)

features:

$$\begin{aligned}\psi_0 &\equiv \int (\bar{Q}_0(1, w) - \bar{Q}_0(0, w)) dQ_{0,W}(w) \\ &= E_{P_0} (E_{P_0}(Y \mid A = 1, W) - E_{P_0}(Y \mid A = 0, W)).\end{aligned}\tag{1}$$

Acting as oracles, we can compute explicitly the numerical value of  $\psi_0$ .

```
integrand <- function(w) {
  Qbar <- attr(five_obs, "Qbar")
  QW <- attr(five_obs, "QW")
  ( Qbar(cbind(1, w)) - Qbar(cbind(0, w)) ) * QW(w)
}
(psi_zero <- integrate(integrand, lower = 0, upper = 1)$val)
```

```
## [1] 0.08317711
```

Our interest in  $\psi_0$  is of causal nature. Taking a closer look at `run_experiment` reveals indeed that the random making of an observation  $O$  drawn from  $P_0$  can be summarized by the following causal graph and nonparametric system of structural equations:

```
dagify(
  Y ~ A + Y1 + Y0, A ~ W, Y1 ~ W, Y0 ~ W,
  labels = c(Y = "Actual reward",
             A = "Action",
             Y1 = "Counterfactual reward\n of action 1",
             Y0 = "Counterfactual reward\n of action 0",
             W = "Context of action"),
  coords = list(
    x = c(W = 0, A = -1, Y1 = 1.5, Y0 = 0.25, Y = 1),
    y = c(W = 0, A = -1, Y1 = -0.5, Y0 = -0.5, Y = -1)),
  outcome = "Y",
  exposure = "A",
  latent = c("Y0", "Y1")) %>% tidy_dagitty %>%
  ggdag(text = TRUE, use_labels = "label") + theme_dag_grey()
```

and, for some deterministic functions  $f_w$ ,  $f_a$ ,  $f_y$  and independent sources of randomness  $U_w$ ,  $U_a$ ,  $U_y$ ,

1. sample the context where the counterfactual rewards will be generated, the action will be undertaken and the actual reward will be obtained,  $W = f_w(U_w)$ ;
2. sample the two counterfactual rewards of the two actions that can be undertaken,  $Y_0 = f_y(0, W, U_y)$  and  $Y_1 = f_y(1, W, U_y)$ ;
3. sample which action is carried out in the given context,  $A = f_a(W, U_a)$ ;
4. define the corresponding reward,  $Y = AY_1 + (1 - A)Y_0$ ;
5. summarize the course of the experiment with the observation  $O = (W, A, Y)$ , thus concealing  $Y_0$  and  $Y_1$ .

The above description of the experiment `run_experiment` is useful to reinforce what it means to run the “ideal” experiment by setting argument `ideal` to `TRUE` in a call to `run_experiment`. Doing so triggers a

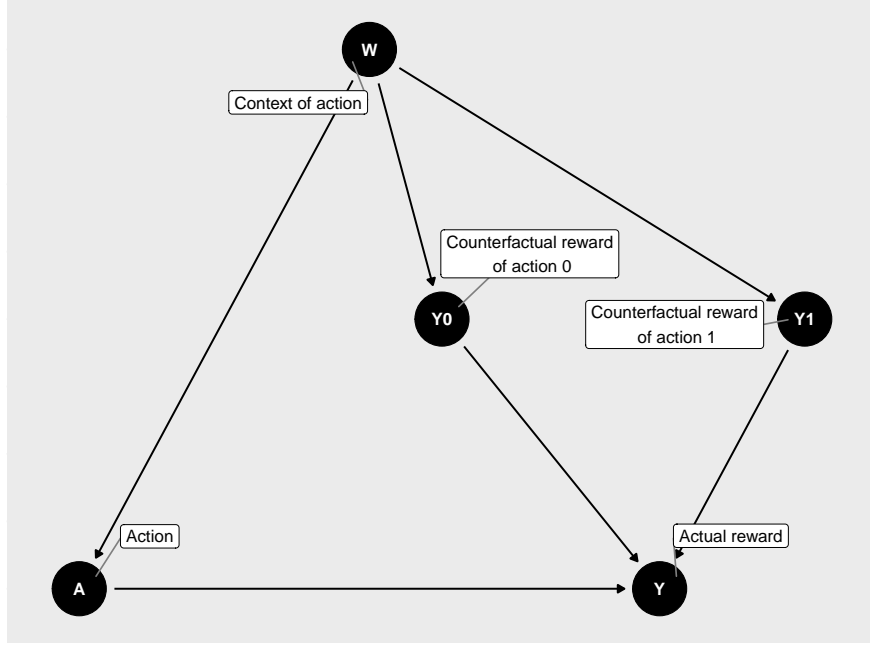

Figure 1: Causal graph summarizing the inner causal mechanism at play in ‘run\_experiment’.

modification of the nature of the experiment, enforcing that the counterfactual rewards  $Y_0$  and  $Y_1$  be part of the summary of the experiment eventually. In light of the above enumeration,  $\mathbb{O} \equiv (W, Y_0, Y_1, A, Y)$  is output, as opposed to its summary measure  $O$ . This defines another experiment and its law, that we denote  $\mathbb{P}_0$ .

It is straightforward to show<sup>†</sup> that

$$\psi_0 = \mathbb{E}_{\mathbb{P}_0}(Y_1 - Y_0) = \mathbb{E}_{\mathbb{P}_0}(Y_1) - \mathbb{E}_{\mathbb{P}_0}(Y_0). \quad (2)$$

Thus,  $\psi_0$  describes the average difference in of the two counterfactual rewards. In other words,  $\psi_0$  quantifies the difference in average of the reward one would get in a world where one would always enforce action  $a = 1$  with the reward one would get in a world where one would always enforce action  $a = 0$ . This said, it is worth emphasizing that  $\psi_0$  is a well-defined parameter beyond its causal interpretation and describes a standardized association between the action  $A$  and the reward  $Y$ .

To conclude this subsection, we use our position as oracles to sample observations from the ideal experiment. We call `run_experiment` with its argument `ideal` set to `TRUE` in order to numerically approximate  $\psi_0$ . By the law of large numbers, the following code approximates  $\psi_0$  and shows its approximate value.

<sup>†</sup>For  $a = 0, 1$ ,

$$\begin{aligned} \mathbb{E}_{\mathbb{P}_0}(Y_a) &= \int \mathbb{E}_{\mathbb{P}_0}(Y_a \mid W = w) dQ_{0,W}(w) = \int \mathbb{E}_{\mathbb{P}_0}(Y_a \mid A = a, W = w) dQ_{0,W}(w) \\ &= \int \mathbb{E}_{P_0}(Y \mid A = a, W = w) dQ_{0,W}(w) = \int \bar{Q}_0(a, W) dQ_{0,W}(w). \end{aligned}$$

The second equality follows from the conditional independence of the counterfactual rewards  $(Y_0, Y_1)$  and action  $A$  given  $W$  (in words, the *randomization assumption* “ $(Y_0, Y_1) \perp A \mid W$ ” is met under  $\mathbb{P}_0$ ). The third equality results from the facts that the observed reward  $Y$  equals the counterfactual reward  $Y_a$  when  $A = a$  (in words, the *consistency assumption* “ $Y_a = Y \mid A = a$ ” is met under  $\mathbb{P}_0$ ) and that  $\Pr_{P_0}(\ell \bar{G}_0(a, W) > 0) = 1$  (in words, the *positivity assumption* is met under  $P_0$  — this is needed for  $\mathbb{E}_{P_0}(Y \mid A = a, W)$  to be well-defined).

```
B <- 1e6
ideal_obs <- run_experiment(B, ideal = TRUE)
(psi_approx <- mean(ideal_obs[, "Yone"] - ideal_obs[, "Yzero"]))
```

```
## [1] 0.08332233
```

The object `psi_approx` contains an approximation to  $\psi_0$  based on `B` observations from the ideal experiment. The random sampling of observations results in uncertainty in the numerical approximation of  $\psi_0$ . This uncertainty can be quantified by constructing a 95% confidence interval for  $\psi_0$ . The central limit theorem and Slutsky's lemma<sup>‡</sup> allow us to build such an interval as follows.

```
sd_approx <- sd(ideal_obs[, "Yone"] - ideal_obs[, "Yzero"])
alpha <- 0.05
(psi_approx_CI <- psi_approx + c(-1, 1) * qnorm(1 - alpha / 2) * sd_approx / sqrt(B))
```

```
## [1] 0.08271472 0.08392994
```

We note that the interpretation of this confidence interval is that in 95% of draws of size `B` from the ideal data generating experiment, the true value of  $\psi_0$  will be contained in the generated confidence interval.

 **2.4 Difference in covariate-adjusted quantile rewards, first pass.** The problems come within the scope of Sections 2.3.

As discussed above, parameter  $\psi_0$  (2) is the difference in average rewards if we enforce action  $a = 1$  rather than  $a = 0$ . An alternative way to describe the rewards under different actions involves quantiles as opposed to averages.

Let  $Q_{0,Y}(y, A, W) = \int_0^y q_{0,Y}(u, A, W) du$  be the conditional cumulative distribution of reward  $Y$  given  $A$  and  $W$ , evaluated at  $y \in ]0, 1[$ , that is implied by  $P_0$ . For each action  $a \in \{0, 1\}$  and  $c \in ]0, 1[$ , introduce

$$\gamma_{0,a,c} \equiv \inf \left\{ y \in ]0, 1[ : \int Q_{0,Y}(y, a, w) dQ_{0,W}(w) \geq c \right\}. \quad (3)$$

It is not difficult to check (see Problem 1 below) that

$$\gamma_{0,a,c} = \inf \{ y \in ]0, 1[ : \Pr_{\mathbb{P}_0}(Y_a \leq y) \geq c \}. \quad (4)$$

Thus,  $\gamma_{0,a,c}$  can be interpreted as a covariate-adjusted  $c$ -th quantile reward when action  $a$  is enforced. The difference

$$\delta_{0,c} \equiv \gamma_{0,1,c} - \gamma_{0,0,c}$$

is the  $c$ -th quantile counterpart to parameter  $\psi_0$  (2).

<sup>‡</sup>Let  $X_1, \dots, X_n$  be independently drawn from a law such that  $\sigma^2 \equiv \text{Var}(X_1)$  is finite. Let  $m \equiv \mathbb{E}(X_1)$  and  $\bar{X}_n \equiv n^{-1} \sum_{i=1}^n X_i$  be the empirical mean. It holds that  $\sqrt{n}(\bar{X}_n - m)$  converges in law as  $n$  grows to the centered Gaussian law with variance  $\sigma^2$ . Moreover, if  $\sigma_n^2$  is a (positive) consistent estimator of  $\sigma^2$ , then  $\sqrt{n}/\sigma_n(\bar{X}_n - m)$  converges in law to the standard normal law. The empirical variance  $n^{-1} \sum_{i=1}^n (X_i - \bar{X}_n)^2$  is such an estimator. In conclusion, denoting by  $\Phi$  the standard normal distribution function,  $[\bar{X}_n \pm \Phi^{-1}(1 - \alpha)\sigma_n/\sqrt{n}]$  is a confidence interval for  $m$  with asymptotic level  $(1 - 2\alpha)$ .

1.  Prove (4).

2.  Compute the numerical value of  $\gamma_{0,a,c}$  for each  $(a, c) \in \{0, 1\} \times \{1/4, 1/2, 3/4\}$  using the appropriate attributes of `five_obs`. Based on these results, report the numerical value of  $\delta_{0,c}$  for each  $c \in \{1/4, 1/2, 3/4\}$ .

3. Approximate the numerical values of  $\gamma_{0,a,c}$  for each  $(a, c) \in \{0, 1\} \times \{1/4, 1/2, 3/4\}$  by drawing a large sample from the “ideal” data experiment and using empirical quantile estimates. Deduce from these results a numerical approximation to  $\delta_{0,c}$  for  $c \in \{1/4, 1/2, 3/4\}$ . Confirm that your results closely match those obtained in the previous problem.

**2.5 The parameter of interest, second pass.** Suppose we know beforehand that  $O$  drawn from  $P_0$  takes its values in  $\mathcal{O} \equiv [0, 1] \times \{0, 1\} \times [0, 1]$  and that  $\bar{G}(W) = P_0(A = 1|W)$  is bounded away from zero and one  $Q_{0,W}$ -almost surely (this is the case indeed). Then we can define model  $\mathcal{M}$  as the set of all laws  $P$  on  $\mathcal{O}$  such that  $\bar{G}(W) \equiv P(A = 1|W)$  is bounded away from zero and one  $Q_W$ -almost surely, where  $Q_W$  is the marginal law of  $W$  under  $P$ .

Let us also define generically  $\bar{Q}$  as

$$\bar{Q}(A, W) \equiv E_P(Y|A, W) ,$$

where, for simplicity, we have suppressed the dependence of  $\bar{Q}$  on  $P$ . Central to our approach is viewing  $\psi_0$  as the value at  $P_0$  of the statistical mapping  $\Psi$  from  $\mathcal{M}$  to  $[0, 1]$  characterized by

$$\begin{aligned} \Psi(P) &\equiv \int (\bar{Q}(1, w) - \bar{Q}(0, w)) dQ_W(w) \\ &= E_P (\bar{Q}(1, W) - \bar{Q}(0, W)) , \end{aligned}$$

a clear extension of (1). For instance, although the law  $\Pi_0 \in \mathcal{M}$  encoded by default (*i.e.*, with `h=0`) in `drawFromAnotherExperiment` defined below differs starkly from  $P_0$ ,

```
run_another_experiment <- function(n, h = 0) {
  ## preliminary
  n <- Arguments$getInteger(n, c(1, Inf))
  h <- Arguments$getNumeric(h)
  ## ## 'Gbar' and 'Qbar' factors
  Gbar <- function(W) {
    sin((1 + W) * pi / 6)
  }
  Qbar <- function(AW, hh = h) {
    A <- AW[, 1]
    W <- AW[, 2]
    expit( logit( A * W + (1 - A) * W^2 ) +
           hh * 10 * sqrt(W) * A )
  }
  ## sampling
  ## ## context
  W <- runif(n, min = 1/10, max = 9/10)
```

```

## ## action undertaken
A <- rbinom(n, size = 1, prob = Gbar(W))
## ## reward
shape1 <- 4
QAW <- Qbar(cbind(A, W))
Y <- rbeta(n, shape1 = shape1, shape2 = shape1 * (1 - QAW) / QAW)
## ## observation
obs <- cbind(W = W, A = A, Y = Y)
attr(obs, "Gbar") <- Gbar
attr(obs, "Qbar") <- Qbar
attr(obs, "QW") <- function(x){dunif(x, min = 1/10, max = 9/10)}

the parameter  $\Psi(\Pi_0)$  is well defined, and numerically approximated by `psi_Pi_zero` as follows.

```

five_obs_from_another_experiment <- run_another_experiment(5)
another_integrand <- function(w) {
  Qbar <- attr(five_obs_from_another_experiment, "Qbar")
  QW <- attr(five_obs_from_another_experiment, "QW")
  ( Qbar(cbind(1, w)) - Qbar(cbind(0, w)) ) * QW(w)
}
(psi_Pi_zero <- integrate(another_integrand, lower = 0, upper = 1)$val)

```

```
## [1] 0.1966687
```

Straightforward algebra confirms that indeed  $\Psi(\Pi_0) = 59/300$ .

 **2.6 Difference in covariate-adjusted quantile rewards, second pass.** We continue with the exercise from Section 2.4. The problems come within the scope of Section 2.3.

As above, we define  $q_Y(y, A, W)$  to be the conditional density of  $Y$  given  $A$  and  $W$ , evaluated at  $y$ , that is implied by a generic  $P \in \mathcal{M}$ . Similarly, we use  $Q_Y$  to denote the corresponding cumulative distribution function. The covariate-adjusted  $c$ -th quantile reward for action  $a \in \{0, 1\}$  may be viewed as a mapping  $\Gamma_{a,c}$  from  $\mathcal{M}$  to  $[0, 1]$  characterized by

$$\Gamma_{a,c}(P) = \inf \left\{ y \in ]0, 1[ : \int Q_Y(y, a, w) dQ_W(w) \geq c \right\}.$$

The difference in  $c$ -th quantile rewards may similarly be viewed as a mapping  $\Delta_c$  from  $\mathcal{M}$  to  $[0, 1]$ , characterized by  $\Delta_c(P) \equiv \Gamma_{1,c}(P) - \Gamma_{0,c}(P)$ .

1. Compute the numerical value of  $\Gamma_{a,c}(\Pi_0)$  for  $(a, c) \in \{0, 1\} \times \{1/4, 1/2, 3/4\}$  using the appropriate

attributes of `five_obs_from_another_experiment`. Based on these results, report the numerical value of  $\Delta_c(\Pi_0)$  for each  $c \in \{1/4, 1/2, 3/4\}$ .

2. Approximate the value of  $\Gamma_{0,a,c}(\Pi_0)$  for  $(a, c) \in \{0, 1\} \times \{1/4, 1/2, 3/4\}$  by drawing a large sample from the “ideal” data experiment and using empirical quantile estimates. Deduce from these results a numerical approximation to  $\Delta_{0,c}(\Pi_0)$  for each  $c \in \{1/4, 1/2, 3/4\}$ . Confirm that your results closely match those obtained in the previous problem.
3. Building upon the code you wrote to solve the previous problem, construct a confidence interval with asymptotic level 95% for  $\Delta_{0,c}(\Pi_0)$ , with  $c \in \{1/4, 1/2, 3/4\}$ .<sup>§</sup>

**2.7 The parameter of interest, third pass.** In the previous subsection, we reoriented our view of the target parameter to be a statistical functional of the law of the observed data. Specifically, we viewed the parameter as a function of specific features of the observed data law, namely  $Q_W$  and  $\bar{Q}$ . It is straightforward<sup>¶</sup> to show an equivalent representation of the parameter as

$$\begin{aligned}\psi_0 &= \int \frac{2a-1}{\ell\bar{G}_0(a, w)} y dP_0(w, a, y) \\ &= E_{P_0} \left( \frac{2A-1}{\ell\bar{G}_0(A, W)} Y \right).\end{aligned}\tag{5}$$

Viewing again the parameter as a statistical mapping from  $\mathcal{M}$  to  $[0, 1]$ , it also holds that

$$\begin{aligned}\Psi(P) &= \int \frac{2a-1}{\ell\bar{G}(a, w)} y dP(w, a, y) \\ &= E_P \left( \frac{2A-1}{\ell\bar{G}_0(A, W)} Y \right).\end{aligned}\tag{6}$$

Our reason for introducing this alternative view of the target parameter will become clear when we discuss estimation of the target parameter. Specifically, the representations (1) and (5) naturally suggest different estimation strategies for  $\psi_0$ . The former suggests building an estimator of  $\psi_0$  using estimators of  $\bar{Q}_0$  and of  $Q_{W,0}$ . The latter suggests building an estimator of  $\psi_0$  using estimators of  $\ell\bar{G}_0$  and of  $P_0$ . We return to these ideas in later sections.

<sup>§</sup>Let  $X_1, \dots, X_n$  be independently drawn from a continuous distribution function  $F$ . Set  $p \in ]0, 1[$  and, assuming that  $n$  is large, find  $k \geq 1$  and  $l \geq 1$  such that  $k/n \approx p - \Phi^{-1}(1-\alpha)\sqrt{p(1-p)/n}$  and  $l/n \approx p + \Phi^{-1}(1-\alpha)\sqrt{p(1-p)/n}$ , where  $\Phi$  is the standard normal distribution function. Then  $[X_{(k)}, X_{(l)}]$  is a confidence interval for  $F^{-1}(p)$  with asymptotic level  $1 - 2\alpha$ .

<sup>¶</sup>We temporarily drop the subscript  $P_0$  to save space and note, for the same reason, that  $(2a-1)$  equals 1 if  $a = 1$  and  $-1$  if  $a = 0$ . Now, for each  $a = 0, 1$ ,

$$\begin{aligned}E \left( \frac{\mathbf{1}\{A=a\}Y}{\ell\bar{G}(a, W)} \right) &= E \left( E \left( \frac{\mathbf{1}\{A=a\}Y}{\ell\bar{G}(a, W)} \middle| A, W \right) \right) = E \left( \frac{\mathbf{1}\{A=a\}}{\ell\bar{G}(a, W)} \bar{Q}(A, W) \right) = E \left( \frac{\mathbf{1}\{A=a\}}{\ell\bar{G}(a, W)} \bar{Q}(a, W) \right) \\ &= E \left( E \left( \frac{\mathbf{1}\{A=a\}}{\ell\bar{G}(a, W)} \bar{Q}(a, W) \middle| W \right) \right) = E \left( \frac{\ell\bar{G}(a, W)}{\ell\bar{G}(a, W)} \bar{Q}(a, W) \middle| W \right) = E \left( \bar{Q}(a, W) \right),\end{aligned}$$

where the first, fourth and sixth equalities follow from the tower rule, and the second and fifth hold by definition of the conditional expectation. This completes the proof.

## 2.8 Difference in covariate-adjusted quantile rewards, third pass. We continue with the exercise from Section 2.4.

1.  Show that for  $a' = 0, 1$ ,  $\gamma_{0,a',c}$  as defined in (3) can be equivalently expressed as

$$\inf \left\{ z \in ]0, 1[ : \int \frac{\mathbf{1}\{a = a'\}}{\ell G(a', W)} \mathbf{1}\{y \leq z\} dP_0(w, a, y) \geq c \right\}.$$

**2.9 Smooth parameters, first pass.** Within our view of the target parameter as a statistical mapping, it is natural to inquire of properties this functional enjoys. For example, we may be interested in asking how the value of  $\Psi(P)$  changes for laws that are, in a loose sense, near to  $P$  in  $\mathcal{M}$ . If small changes in the law result in large changes in the parameter value, then we might hypothesize that it will be difficult to produce “good estimators” of  $\psi_0$ . Fortunately, this turns out not to be the case for  $\Psi$ , and so we say that  $\Psi$  is a smooth parameter mapping. This colloquial expression refers to the fact that, for each  $P \in \mathcal{M}$ , if  $P_h \rightarrow_h P$  in  $\mathcal{M}$  from a direction  $s$  when the real parameter  $h \rightarrow 0$  (the notion of convergence from a direction is formalized in Section 2.10), then not only  $\Psi(P_h) \rightarrow_h \Psi(P)$  (continuity), but also  $h^{-1}[\Psi(P_h) - \Psi(P)] \rightarrow_h c$ , where the real number  $c$  depends on  $P$  and  $s$  (differentiability).

For instance, let  $\Pi_h \in \mathcal{M}$  be the law encoded in `run_another_experiment` with `h` ranging over  $[-1, 1]$ . We will argue shortly that  $\Pi_h \rightarrow_h \Pi_0$  in  $\mathcal{M}$  from a direction  $s$  when  $h \rightarrow 0$ . The following chunk of code evaluates and represents  $\Psi(\Pi_h)$  for  $h$  ranging in a discrete approximation of  $[-1, 1]$ :

```
approx <- seq(-1, 1, length.out = 1e2)
psi_Pi_h <- sapply(approx, function(t) {
  obs_from_another_experiment <- run_another_experiment(1, h = t)
  integrand <- function(w) {
    Qbar <- attr(obs_from_another_experiment, "Qbar")
    QW <- attr(obs_from_another_experiment, "QW")
    ( Qbar(cbind(1, w)) - Qbar(cbind(0, w)) ) * QW(w)
  }
  integrate(integrand, lower = 0, upper = 1)$val
})
slope_approx <- (psi_Pi_h - psi_Pi_zero) / approx
slope_approx <- slope_approx[min(which(approx > 0))]
ggplot() +
  geom_point(data = data.frame(x = approx, y = psi_Pi_h), aes(x, y),
    color = "#CC6666") +
  geom_segment(aes(x = -1, y = psi_Pi_zero - slope_approx,
    xend = 1, yend = psi_Pi_zero + slope_approx),
    arrow = arrow(length = unit(0.03, "npc")),
    color = "#9999CC") +
  geom_vline(xintercept = 0, color = "#66CC99") +
  geom_hline(yintercept = psi_Pi_zero, color = "#66CC99") +
  labs(x = "h", y = expression(Psi(Pi[h])))
```

The dotted curve represents the function  $h \mapsto \Psi(\Pi_h)$ . The blue line represents the tangent to the previous curve at  $h = 0$ , which is indeed differentiable around  $h = 0$ . It is derived by simple geometric arguments. In the next subsection, we formalize what it means to be smooth for the statistical mapping  $\Psi$ . This allows us to derive a closed-form expression for the slope of the blue curve from the chunk of code where `run_another_experiment` is defined.

Figure 2: Evolution of statistical parameter  $\Psi$  along fluctuation  $\{\Pi_h : h \in H\}$ .

**2.10**  **Being smooth, second pass.** Let us now describe what it means for statistical mapping  $\Psi$  to be smooth at every  $P \in \mathcal{M}$ . To describe the rate of change of a statistical parameter at  $P$  as  $P$  is approached in model  $\mathcal{M}$ , we must formalize what is meant by “approach  $P$ ”. Toward that end, we introduce the idea of fluctuations of  $P$ . For every  $h \in H \equiv ]-M^{-1}, M^{-1}[$ , we can define a law  $P_h \in \mathcal{M}$  by setting  $P_h \ll P^\parallel$  and

$$\frac{dP_h}{dP} \equiv 1 + hs, \quad (7)$$

where  $s : \mathcal{O} \rightarrow \mathbb{R}$  is a (measurable) function of  $O$  such that  $s(O)$  is not equal to zero  $P$ -almost surely,  $E_P(s(O)) = 0$ , and  $s$  bounded by  $M$ . We make the observation that

$$(i) \ P_h|_{h=0} = P, \quad (ii) \ \left. \frac{d}{dh} \log \frac{dP_h}{dP}(O) \right|_{h=0} = s(O). \quad (8)$$

Because of (i), we say that  $\{P_h : h \in H\}$  is a *fluctuation* of  $P$ . The fluctuation is a one-dimensional submodel of  $\mathcal{M}$  with univariate parameter  $h \in H$ . We note that (ii) indicates that the score of this submodel at  $h = 0$  is  $s$ . Thus, we say that the fluctuation is *in the direction* of  $s$ . Fluctuations of  $P$  do not necessarily take the same form as in (7). No matter how the fluctuation is built, what really matters is its local shape in the neighborhood of  $P$ .

We are now prepared to provide a formal definition of smoothness of statistical mappings. **Please check these modifications.** We say that a statistical mapping  $\Psi$  is smooth at every  $P \in \mathcal{M}$  if for each  $P \in \mathcal{M}$ , there exists a (measurable) function  $D^*(P) : \mathcal{O} \rightarrow \mathbb{R}$  such that  $E_P(D^*(P)(O)) = 0$ ,  $\text{Var}_P(D^*(P)(O))$  finite and, for every fluctuation  $\{P_h : h \in H\}$  with score  $s$  at  $h = 0$ , the real-valued mapping  $h \mapsto \Psi(P_h)$  is differentiable at  $h = 0$ , with a derivative equal to

$$E_P(D^*(P)(O)s(O)). \quad (9)$$

Interestingly, if a fluctuation  $\{P_h : h \in H\}$  satisfies (8) for a direction  $s$  such that  $s \neq 0$ ,  $E_P(s(O)) = 0$  and  $\text{Var}_P(s(O)) < \infty$ , then  $h \mapsto \Psi(P_h)$  is still differentiable at  $h = 0$  with a derivative equal to (9) (beyond fluctuations of the form (7)). **Maybe this needs reconciliation with my above modifications, as I'm defining things for a general fluctuation. Hmm...**

---

<sup>||</sup>That is,  $P_h$  is dominated by  $P$ : if an event  $A$  satisfies  $P(A) = 0$ , then necessarily  $P_h(A) = 0$  too.

The object  $D^*(P)$  in (9) is called a gradient of  $\Psi$  at  $P$ . This terminology has a direct parallel to directional derivatives in the calculus of Euclidean geometry. That is, if  $f : \mathbb{R}^p \rightarrow \mathbb{R}$ ,  $u$  is a unit vector in  $\mathbb{R}^p$ , and  $x$  is a point in  $\mathbb{R}^p$ , the directional derivative at  $x$  in the direction  $u$  is the dot product of the gradient of  $f$  and  $u$ . That is, the derivative can be represented as an inner product of the direction that we approach  $x$  and the change of the function's value at  $x$ . In the present problem, the law  $P$  is the point at which we evaluate the function, the score  $s$  of the fluctuation is the “direction” in which we approach the point, and the gradient describes the change in the function's value at the point.

Need a transition to calling this an influence function or influence curve. Right now, it seems a little out of place to be talking about estimation at this point since the section is all about being smooth, which is a property of parameters, not estimators. Maybe we move the next paragraphs to the following section and re-title it something like "Influence functions and efficient influence functions" or something? Not sure. Need to think about it more.

The influence curves  $D^*(P)$  convey valuable information about  $\Psi$ . For instance, an important result from the theory of inference based on semiparametric models guarantees that if  $\psi_n$  is a regular\*\* estimator of  $\Psi(P)$  built from  $n$  independent observations drawn from  $P$ , then the asymptotic variance of the centered and rescaled  $\sqrt{n}(\psi_n - \Psi(P))$  cannot be smaller than the variance of the  $P$ -specific efficient influence curve, that is,

$$\text{Var}_P(D^*(P)(O)). \quad (10)$$

In this light, an estimator  $\psi_n$  of  $\Psi(P)$  is said *asymptotically efficient* at  $P$  if it is regular at  $P$  and such that  $\sqrt{n}(\psi_n - \Psi(P))$  converges in law to the centered Gaussian law with variance (10), which is called the Cramér-Rao bound.

**2.11 The efficient influence curve.** It is not difficult to check (do we give the proof?) that the efficient influence curve  $D^*(P)$  of  $\Psi$  at  $P \in \mathcal{M}$  writes as  $D^*(P) \equiv D_1^*(P) + D_2^*(P)$  where  $D_1^*(P)$  and  $D_2^*(P)$  are given by

$$\begin{aligned} D_1^*(P)(O) &\equiv \bar{Q}(1, W) - \bar{Q}(0, W) - \Psi(P), \\ D_2^*(P)(O) &\equiv \frac{2A - 1}{\ell \bar{G}(A, W)} (Y - \bar{Q}(A, W)). \end{aligned}$$

The following chunk of code enables the computation of the values of the efficient influence curve  $D^*(P)$  at observations drawn from  $P$  (note that it is necessary to provide the value of  $\Psi(P)$ , or a numerical approximation thereof, through argument `psi`).

```
eic <- function(obs, psi) {
  Qbar <- attr(obs, "Qbar")
  Gbar <- attr(obs, "Gbar")
  QAW <- Qbar(obs[, c("A", "W")])
  QoneW <- Qbar(cbind(A = 1, W = obs[, "W"]))
  QzeroW <- Qbar(cbind(A = 0, W = obs[, "W"]))
```

\*\*We can view  $\psi_n$  as the by product of an algorithm  $\hat{\Psi}$  trained on independent observations  $O_1, \dots, O_n$  drawn from  $P$ . The estimator is regular at  $P$  (w.r.t. the maximal tangent space) if, for any direction  $s \neq 0$  such that  $E_P(s(O)) = 0$  and  $\text{Var}_P(s(O)) < \infty$  and fluctuation  $\{P_h : h \in H\}$  satisfying (8), the estimator  $\psi_{n,1/\sqrt{n}}$  of  $\Psi(P_{1/\sqrt{n}})$  obtained by training  $\hat{\Psi}$  on independent observations  $O_1, \dots, O_n$  drawn from  $P_{1/\sqrt{n}}$  is such that  $\sqrt{n}(\psi_{n,1/\sqrt{n}} - \Psi(P_{1/\sqrt{n}}))$  converges in law to a limit that does not depend on  $s$ .

```

GW <- Gbar(obs[, "W", drop = FALSE])
lGAW <- obs[, "A"] * GW + (1 - obs[, "A"]) * (1 - GW)
out <- (QoneW - QzeroW - psi) + (2 * obs[, "A"] - 1) / lGAW * (obs[, "Y"] - QAW)
out <- as.vector(out)
return(out)
}

```

```
(eic(five_obs, psi = psi_approx))
```

```
## [1] -1.0158313 -0.9023582 -0.3263940 0.2453818 -1.2682788
```

```
(eic(five_obs_from_another_experiment, psi = psi_Pi_zero))
```

```
## [1] -0.01734850 -0.16604772 -0.02136035 -0.10072902 0.10201463
```

**2.12 Computing and comparing Cramér-Rao bounds.** We can use `eic` to numerically approximate the Cramér-Rao bound at  $P_0$ :

```

obs <- run_experiment(B)
(cramer_rao_hat <- var(eic(obs, psi = psi_approx)))

```

```
## [1] 0.2863057
```

and the Cramér-Rao bound at  $\Pi_0$ :

```

obs_from_another_experiment <- run_another_experiment(B)
(cramer_rao_Pi_zero_hat <- var(eic(obs_from_another_experiment, psi = 59/300)))

```

```
## [1] 0.0952758
```

```
(ratio <- sqrt(cramer_rao_Pi_zero_hat/cramer_rao_hat))
```

```
## [1] 0.5768678
```

We thus discover that of the statistical parameters  $\Psi(P_0)$  and  $\Psi(\Pi_0)$ , the latter is easier to target than the former. Heuristically, for large sample sizes, the narrowest (efficient) confidence intervals for  $\Psi(\Pi_0)$  are approximately 0.58 (rounded to two decimal places) smaller than their counterparts for  $\Psi(P_0)$ .

**2.13 Revisiting Section 2.9.** It is not difficult either (though a little cumbersome) (do we give the proof? I'd rather not) to verify that  $\{\Pi_h : h \in [-1, 1]\}$  is a fluctuation of  $\Pi_0$  in the direction of  $\sigma_0$  (in the sense of (7)) given, up to a constant, by

$$\sigma_0(O) \equiv -10\sqrt{W}A \times \beta_0(A, W) \left( \log(1 - Y) + \sum_{k=0}^3 (k + \beta_0(A, W))^{-1} \right) + \text{constant},$$

where  $\beta_0(A, W) \equiv \frac{1 - \bar{Q}_{\Pi_0}(A, W)}{\bar{Q}_{\Pi_0}(A, W)}.$

Consequently, the slope of the dotted curve in Figure 2 is equal to

$$E_{\Pi_0}(D^*(\Pi_0)(O)\sigma_0(O)) \quad (11)$$

(since  $D^*(\Pi_0)$  is centered under  $\Pi_0$ , knowing  $\sigma_0$  up to a constant is not problematic).

Let us check this numerically. In the next chunk of code, we implement direction  $\sigma_0$  with `sigma0_run_another_experiment`, then we numerically approximate (11) (pointwise and with a confidence interval of asymptotic level 95%):

```
sigma0_run_another_experiment <- function(obs) {
  ## preliminary
  Qbar <- attr(obs, "Qbar")
  QAW <- Qbar[obs[, c("A", "W")]]
  shape1 <- Arguments$getInteger(attr(obs, "shape1"), c(1, Inf))
  ## computations
  betaAW <- shape1 * (1 - QAW) / QAW
  out <- log(1 - obs[, "Y"])
  for (int in 1:shape1) {
    out <- out + 1/(int - 1 + betaAW)
  }
  out <- - out * shape1 * (1 - QAW) / QAW * 10 * sqrt(obs[, "W"]) * obs[, "A"]
  ## no need to center given how we will use it
  return(out)
}

vars <- eic(obs_from_another_experiment, psi = 59/300) *
  sigma0_run_another_experiment(obs_from_another_experiment)
sd_hat <- sd(vars)
(slope_hat <- mean(vars))
```

```
## [1] 1.360481
```

```
(slope_CI <- slope_hat + c(-1, 1) * qnorm(1 - alpha / 2) * sd_hat / sqrt(B))
```

```
## [1] 1.355199 1.365762
```

Equal to 1.349 (rounded to three decimal places), the first numerical approximation `slope_approx` is not too off.

**2.14 Double-robustness** The efficient influence curve  $D^*(P)$  at  $P \in \mathcal{M}$  enjoys another remarkable property: it is double-robust. Specifically, if we define for all  $P' \in \mathcal{M}$

$$\text{Rem}_P(\bar{Q}', \bar{G}') \equiv \Psi(P') - \Psi(P) + E_P(D^*(P')(O)), \quad (12)$$

then the so called remainder term  $\text{Rem}_P(\bar{Q}', \bar{G}')$  satisfies<sup>††</sup>

$$\text{Rem}_P(\bar{Q}', \bar{G}')^2 \leq \|\bar{Q}' - \bar{Q}\|_P^2 \times \|(\bar{G}' - \bar{G})/\ell\bar{G}'\|_P^2. \quad (13)$$

In particular, if

---

<sup>††</sup>For any (measurable)  $f : \mathcal{O} \rightarrow \mathbb{R}$ , we denote  $\|f\|_P = E_P(f(O)^2)^{1/2}$ .

$$E_P(D^*(P')(O)) = 0, \quad (14)$$

and *either*  $\bar{Q}' = \bar{Q}$  *or*  $\bar{G}' = \bar{G}$ , then  $\text{Rem}_P(\bar{Q}', \bar{G}') = 0$  hence  $\Psi(P') = \Psi(P)$ . In words, if  $P'$  solves the so called  $P$ -specific efficient influence curve equation (14) and if, in addition,  $P'$  has the same  $\bar{Q}$ -component or  $\bar{G}$ -component as  $P$ , then  $\Psi(P') = \Psi(P)$  no matter how  $P'$  may differ from  $P$  otherwise. This property is useful to build consistent estimators of  $\Psi(P)$ .

However, there is much more to double-robustness than the above straightforward implication. Indeed, 12 is useful to build a consistent estimator of  $\Psi(P)$  that, in addition, satisfies a central limit theorem and thus lends itself to the construction of confidence intervals.

Let  $P_n^0 \in \mathcal{M}$  be an element of model  $\mathcal{M}$  of which the choice is data-driven, based on observing  $n$  independent draws from  $P$ . Equality 12 reveals that the statistical behavior of the corresponding *substitution* estimator  $\psi_n^0 \equiv \Psi(P_n^0)$  is easier to analyze when the remainder term  $\text{Rem}_P(\bar{Q}_n^0, \bar{G}_n^0)$  goes to zero at a fast (relative to  $n$ ) enough rate. In light of 13, this happens if the features  $\bar{Q}_n^0$  and  $\bar{G}_n^0$  of  $P_n^0$  converge to their counterparts under  $P$  at rates of which *the product* is fast enough.

**2.15 Inference assuming  $\bar{G}_0$  known, or not, first pass.** Let  $O_1, \dots, O_n$  be a sample of independent observations drawn from  $P_0$ . Let  $P_n$  be the corresponding empirical measure, *i.e.*, the law consisting in drawing one among  $O_1, \dots, O_n$  with equal probabilities  $n^{-1}$ .

Let us assume for a moment that we know  $\bar{G}_0$ . This may be the case indeed if  $P_0$  was a controlled experiment. Note that, on the contrary, assuming  $\bar{Q}_0$  known would be difficult to justify.

```
Gbar <- attr(obs, "Gbar")
```

```
iter <- 1e3
```

Then, the alternative expression 5 suggests to estimate  $\psi_0$  with

$$\psi_n^b \equiv E_{P_n} \left( \frac{2A-1}{\ell_{\bar{G}_0}(A, W)} Y \right) = \frac{1}{n} \sum_{i=1}^n \left( \frac{2A_i-1}{\ell_{\bar{G}_0}(A_i, W_i)} Y_i \right). \quad (15)$$

Note how  $P_n$  is substituted for  $P_0$  in (15) relative to (5).

It is easy to check that  $\psi_n^b$  estimates  $\psi_0$  consistently, but this is too little to request from an estimator of  $\psi_0$ . Better,  $\psi_n^b$  also satisfies a central limit theorem:  $\sqrt{n}(\psi_n^b - \psi_0)$  converges in law to a centered Gaussian law with asymptotic variance

$$v^b \equiv \text{Var}_{P_0} \left( \frac{2A-1}{\ell_{\bar{G}_0}(A, W)} Y \right),$$

where  $v^b$  can be consistently estimated by its empirical counterpart

$$v_n^b \equiv \text{Var}_{P_n} \left( \frac{2A-1}{\ell_{\bar{G}_0}(A, W)} Y \right) = \frac{1}{n} \sum_{i=1}^n \left( \frac{2A_i-1}{\ell_{\bar{G}_0}(A_i, W_i)} Y_i - \psi_n^b \right)^2. \quad (16)$$

Let us investigate how  $\psi_n^b$  behaves based on `obs`. Because we are interested in the *law* of  $\psi_n^b$ , the next chunk of code constitutes `iter` = 1000 independent samples of independent observations drawn from  $P_0$ , each consisting of  $n$  equal to `nrow(obs)/iter` = 1000 data points, and computes the realization of  $\psi_n^b$  on all samples.

Before proceeding, let us introduce

$$\begin{aligned}\psi_n^a &\equiv E_{P_n}(Y|A=1) - E_{P_n}(Y|A=0) \\ &= \frac{1}{n_1} \sum_{i=1}^n \mathbf{1}\{A_i = 1\} Y_i - \frac{1}{n_0} \sum_{i=1}^n \mathbf{1}\{A_i = 0\} Y_i \\ &= \frac{1}{n_1} \sum_{i=1}^n A_i Y_i - \frac{1}{n_0} \sum_{i=1}^n (1 - A_i) Y_i,\end{aligned}$$

where  $n_1 = \sum_{i=1}^n A_i = n - n_0$  is the number of observations  $O_i$  such that  $A_i = 1$ . It is an estimator of

$$E_{P_0}(Y|A=1) - E_{P_0}(Y|A=0).$$

We seize this opportunity to demonstrate numerically the obvious fact that  $\psi_n^a$  does not estimate  $\psi_0$ .

```
psi_hat_ab <- obs %>% as_tibble() %>%
  mutate(id = (seq_len(n()) - 1) %% iter) %>%
  mutate(lGAW = A * Gbar(W) + (1 - A) * (1 - Gbar(W))) %>% group_by(id) %>%
  summarize(est_a = mean(Y[A==1]) - mean(Y[A==0]),
            est_b = mean(Y * (2 * A - 1) / lGAW),
            std_b = sd(Y * (2 * A - 1) / lGAW) / sqrt(n()),
            clt_b = (est_b - psi_approx) / std_b) %>%
  mutate(std_a = sd(est_a),
         clt_a = (est_a - psi_approx) / std_a) %>%
  gather("key", "value", -id) %>%
  extract(key, c("what", "type"), "([^-_]+)_([ab])") %>%
  spread(what, value)

(bias_ab <- psi_hat_ab %>% group_by(type) %>% summarise(bias = mean(clt)))
```

```
## # A tibble: 2 x 2
##   type   bias
##   <chr> <dbl>
## 1 a     1.43
## 2 b     0.0665
```

```
fig <- ggplot() +
  geom_line(aes(x = x, y = y),
            data = tibble(x = seq(-3, 3, length.out = 1e3),
                          y = dnorm(x)),
            linetype = 1, alpha = 0.5) +
  geom_density(aes(clt, fill = type, colour = type),
              psi_hat_ab, alpha = 0.1) +
  geom_vline(aes(xintercept = bias, colour = type),
            bias_ab, size = 1.5, alpha = 0.5)
```

Figure 3: Kernel density estimators of the law of two estimators of  $\psi_0$  (recentered with respect to  $\psi_0$ , and renormalized), one of them misconceived (a), the other assuming that  $\bar{G}_0$  is known (b). Built based on `iter` independent realizations of each estimator.

```
fig +
  labs(y = "",
       x = expression(paste(sqrt(n/v[n]^{list(a, b)})*(psi[n]^{list(a, b)} - psi[0]))))
```

Let  $v_n^a$  be  $n$  times the empirical variance of the `iter` realizations of  $\psi_n^a$ . By the above chunk of code, the averages of  $\sqrt{n/v_n^a}(\psi_n^a - \psi_0)$  and  $\sqrt{n/v_n^b}(\psi_n^b - \psi_0)$  computed across the realizations of the two estimators are respectively equal to 1.425 and 0.067 (both rounded to three decimal places — see `bias_ab`). Interpreted as amounts of bias, those two quantities are represented by vertical lines in Figure 3. The red and blue bell-shaped curves represent the empirical laws of  $\psi_n^a$  and  $\psi_n^b$  (recentered with respect to  $\psi_0$ , and renormalized) as estimated by kernel density estimation. The latter is close to the black curve, which represents the standard normal density.

**2.16 Inference assuming  $\bar{G}_0$  known, or not, second pass.** At the beginning of Section 2.15, we assumed that  $\bar{G}_0$  was known. Let us suppose now that it is not. The definition of  $\psi_n^b$  can be adapted to overcome this difficulty, by substituting an estimator of  $\ell\bar{G}_0$  for  $\ell\bar{G}_0$  in (15).

For simplicity, we consider the case that  $\bar{G}_0$  is estimated by minimizing a loss function on a single working model, both fine-tune-parameter-free. By adopting this stance, we exclude estimating procedures that involve penalization (*e.g.* the LASSO) or aggregation of competing estimators (*via* stacking/super learning) — see Section 2.17. Defined in the next chunk of code, the generic function `estimate_G` fits a user-specified working model by minimizing the empirical risk associated to the user-specified loss function and provided data.

*Comment on new structure of `estimate_G` and say a few words about `compute_lGhatAW`.*

```
estimate_G <- function(dat, algorithm, ...) {
  if (!is.data.frame(dat)) {
    dat <- as.data.frame(dat)
  }
  if (!attr(algorithm, "ML")) {
    fit <- algorithm[[1]](formula = algorithm[[2]], data = dat)
  } else {
    fit <- algorithm[[1]](dat, ...)
  }
}
```

```

fit$type_of_preds <- algorithm$type_of_preds
return(fit)
}

compute_lGhatAW <- function(A, W, Ghat, threshold = 0.05) {
  dat <- data.frame(A = A, W = W)
  Ghat_W <- predict(Ghat, newdata = dat, type = Ghat$type_of_preds)
  lGAW <- A * Ghat_W + (1 - A) * (1 - Ghat_W)
  pred <- pmin(1 - threshold, pmax(lGAW, threshold))
  return(pred)
}

```

Note how the prediction of any  $\ell_{\bar{G}_0}(A, W)$  is manually bounded away from 0 and 1 at the last but one line of `compute_lGhatAW`. This is desirable because the *inverse* of each  $\ell_{\bar{G}_0}(A_i, W_i)$  appears in the definition of  $\psi_n^b$  (15).

For sake of illustration, we choose argument `working_model_G_one` of function `estimate_G` as follows:

```

trim_glm_fit <- caret::getModelInfo("glm")$glm$trim
working_model_G_one <- list(
  model = function(...) {trim_glm_fit(glm(family = binomial(), ...))},
  formula = as.formula(
    paste("A ~",
          paste(c("I(W^", "I(abs(W - 5/12)^"),
                rep(seq(1/2, 3/2, by = 1/2), each = 2),
                sep = "", collapse = ") + "),
          ")")
    ),
  type_of_preds = "response"
)
attr(working_model_G_one, "ML") <- FALSE
working_model_G_one$formula

## A ~ I(W^0.5) + I(abs(W - 5/12)^0.5) + I(W^1) + I(abs(W - 5/12)^1) +
##      I(W^1.5) + I(abs(W - 5/12)^1.5)

```

In words, we choose the so called logistic (or negative binomial) loss function  $L_a$  given by

$$-L_a(f)(A, W) \equiv A \log f(W) + (1 - A) \log(1 - f(W)) \quad (17)$$

for any function  $f : [0, 1] \rightarrow [0, 1]$  paired with the working model  $\mathcal{F} \equiv \{f_\theta : \theta \in \mathbb{R}^5\}$  where, for any  $\theta \in \mathbb{R}^5$ ,  $\text{logit } f_\theta(W) \equiv \theta_0 + \sum_{j=1}^4 \theta_j W^{j/2}$ . The working model is well specified: it happens that  $\bar{G}_0$  is the unique minimizer of the risk entailed by  $L_a$  over  $\mathcal{F}$ :

$$\bar{G}_0 = \arg \min_{f_\theta \in \mathcal{F}} E_{P_0} (L_a(f_\theta)(A, W)).$$

Therefore, the estimator  $\bar{G}_n$  output by `estimate_G` and obtained by minimizing the empirical risk

$$E_{P_n}(L_a(f_\theta)(A, W)) = \frac{1}{n} \sum_{i=1}^n L_a(f_\theta)(A_i, W_i)$$

over  $\mathcal{F}$  consistently estimates  $\bar{G}_0$ .

In light of (15), introduce

$$\psi_n^c \equiv \frac{1}{n} \sum_{i=1}^n \left( \frac{2A_i - 1}{\ell \bar{G}_n(A_i, W_i)} Y_i \right). \quad (18)$$

Because  $\bar{G}_n$  minimizes the empirical risk over a finite-dimensional and well-specified working model,  $\sqrt{n}(\psi_n^c - \psi_0)$  converges in law to a centered Gaussian law. Let us compute  $\psi_n^c$  on the same `iter` = 1000 independent samples of independent observations drawn from  $P_0$  as in Section 2.15:

```
if (redo_fixed) {
  learned_features_fixed_sample_size <-
    obs %>% as_tibble() %>%
    mutate(id = (seq_len(n()) - 1) %% iter) %>%
    nest(-id, .key = "obs") %>%
    mutate(Ghat = map(obs, ~ estimate_G(., algorithm = working_model_G_one))) %>%
    mutate(lGAW = map2(Ghat, obs, ~ compute_lGhatAW(.y$A, .y$W, .x)))
}

psi_hat_abc <-
  learned_features_fixed_sample_size %>%
  unnest(obs, lGAW) %>%
  group_by(id) %>%
  summarize(est = mean(Y * (2 * A - 1) / lGAW)) %>%
  mutate(std = sd(est),
         clt = (est - psi_approx) / std,
         type = "c") %>%
  full_join(psi_hat_ab)

(bias_abc <- psi_hat_abc %>% group_by(type) %>% summarise(bias = mean(clt)))

## # A tibble: 3 x 2
##   type    bias
##   <chr>   <dbl>
## 1 a      1.43
## 2 b      0.0665
## 3 c     -0.0172
```

Note how we exploit the independent realizations of  $\psi_n^c$  to estimate the asymptotic variance of the estimator with  $v_n^c/n$ . By the above chunk of code, the average of  $\sqrt{n}/v_n^c(\psi_n^c - \psi_0)$  computed across the realizations is equal to -0.017 (rounded to three decimal places — see `bias_abc`). We represent the empirical laws of the recentered (with respect to  $\psi_0$ ) and renormalized  $\psi_n^a$ ,  $\psi_n^b$  and  $\psi_n^c$  in Figures 4 (kernel density estimators) and 5 (quantile-quantile plots).

```
fig +
  geom_density(aes(clt, fill = type, colour = type), psi_hat_abc, alpha = 0.1) +
  geom_vline(aes(xintercept = bias, colour = type),
```

Figure 4: Kernel density estimators of the law of three estimators of  $\psi_0$  (recentered with respect to  $\psi_0$ , and renormalized), one of them misconceived (a), one assuming that  $\bar{G}_0$  is known (b) and one that hinges on the estimation of  $\bar{G}_0$  (c). The present figure includes Figure 3 (but the colors differ). Built based on `iter` independent realizations of each estimator.

Figure 5: Quantile-quantile plot of the standard normal law against the empirical laws of three estimators of  $\psi_0$ , one of them misconceived (a), one assuming that  $\bar{G}_0$  is known (b) and one that hinges on the estimation of  $\bar{G}_0$  (c). Built based on `iter` independent realizations of each estimator.

```

      bias_abc, size = 1.5, alpha = 0.5) +
  xlim(-3, 4) +
  labs(y = "",
       x = expression(paste(sqrt(n/v[n]^list(a, b, c))*
                           (psi[n]^list(a, b, c) - psi[0]))))

ggplot(psi_hat_abc, aes(sample = clt, fill = type, colour = type)) +
  geom_abline(intercept = 0, slope = 1, alpha = 0.5) +
  geom_qq(alpha = 1)

```

Figures 4 and 5 reveal that  $\psi_n^c$  behaves as well as  $\psi_n^b$  — but remember that we did not discuss how to estimate its asymptotic variance.

## 2.17 Exercises. The problems come within the context of Sections 2.15 and 2.16.

1. Compute a numerical approximation of  $E_{P_0}(Y|A = 1) - E_{P_0}(Y|A = 0)$ . How accurate is it?
2. Building upon the piece of code devoted to the repeated computation of  $\psi_n^b$  and its companion quantities, construct confidence intervals for  $\psi_0$  of (asymptotic) level 95%, and check if the empirical coverage is satisfactory. Note that if the coverage was exactly 95%, then the number of confidence intervals that would contain  $\psi_0$  would follow a binomial law with parameters `iter` and 0.95, and recall that function `binom.test` performs an exact test of a simple null hypothesis about the probability of success in a Bernoulli experiment against its three one-sided and two-sided alternatives.
3. The call to `compute_lGhatAW` makes predictions on the same data points as those exploited to learn  $\bar{G}_0$  by fitting the user-supplied working model. Why could that be problematic? Can you think of a simple workaround, implement and test it?
4. Discuss what happens when the dimension of the (still well-specified) working model grows. You could use the following chunk of code

```
powers <- ## make sure '1/2' and '1' belong to 'powers', eg
seq(1/4, 3, by = 1/4)
working_model_G_two <- list(
  model = function(...) {trim_glm_fit(glm(family = binomial(), ...))},
  formula = as.formula(
    paste("A ~",
          paste(c("I(W~", "I(abs(W - 5/12)~"),
                rep(powers, each = 2),
                sep = "", collapse = ") + "),
          ")")
  ),
  type_of_preds = "response"
)
attr(working_model_G_two, "ML") <- FALSE
```

play around with argument `powers` (making sure that 1/2 and 1 belong to it), and plot graphics similar to those presented in Figures 4 and 5.

5. Discuss what happens when the working model is mis-specified. You could use the following chunk of code:

```
transform <- c("cos", "sin", "sqrt", "log", "exp")
working_model_G_three <- list(
  model = function(...) {trim_glm_fit(glm(family = binomial(), ...))},
  formula = as.formula(
    paste("A ~",
          paste("I(", transform, sep = "", collapse = "(W)) + "),
          "(W))")
  ),
  type_of_preds = "response"
)
attr(working_model_G_three, "ML") <- FALSE
(working_model_G_three$formula)
```

```
## A ~ I(cos(W)) + I(sin(W)) + I(sqrt(W)) + I(log(W)) + I(exp(W))
```

6.  Drawing inspiration from (16), one may consider estimating the asymptotic variance of  $\psi_n^c$  with the counterpart of  $v_n^b$  obtained by substituting  $\ell\bar{G}_n$  for  $\ell\bar{G}_0$  in (16). By adapting the piece of code devoted

to the repeated computation of  $\psi_n^b$  and its companion quantities, discuss if that would be legitimate.

**2.18 Inference based on the estimation of  $\bar{Q}_0$ .** Comment on structure of `estimate_Q`, similar to that of `estimate_G`.

Demonstrating the inference of  $\psi_0$  based on the estimation of  $\bar{Q}_0$  (and of the marginal law of  $W$ ). Once based on a (mis-specified) working model, and once based on a non-parametric algorithm.

```
estimate_Q <- function(dat, algorithm, ...) {
  if (!is.data.frame(dat)) {
    dat <- as.data.frame(dat)
  }
  if (!attr(algorithm, "ML")) {
    fit <- algorithm[[1]](formula = algorithm[[2]], data = dat)
  } else {
    fit <- algorithm[[1]](dat, ...)
  }
  fit$type_of_preds <- algorithm$type_of_preds
  return(fit)
}

compute_QhatAW <- function(Y, A, W, Qhat, blip = FALSE) {
  if (!blip) {
    dat <- data.frame(Y = Y, A = A, W = W)
    pred <- predict(Qhat, newdata = dat, type = Qhat$type_of_preds)
  } else {
    pred <- predict(Qhat, newdata = data.frame(A = 1, W = W),
                  type = Qhat$type_of_preds) -
      predict(Qhat, newdata = data.frame(A = 0, W = W),
              type = Qhat$type_of_preds)
  }
  return(pred)
}

working_model_Q_one <- list(
  model = function(...) {trim_glm_fit(glm(family = binomial(), ...))},
  formula = as.formula(
    paste("Y ~ A * (",
          paste("I(W~", seq(1/2, 3/2, by = 1/2), sep = "", collapse = ") + ",
                ")))")
  ),
  type_of_preds = "response"
)
attr(working_model_Q_one, "ML") <- FALSE
working_model_Q_one$formula
```

```
## Y ~ A * (I(W^0.5) + I(W^1) + I(W^1.5))
```

```
## k-NN
```

```
kknn_algo <- list(
  algo = function(dat, ...) {
    args <- list(...)
    if ("Subsample" %in% names(args)) {
```

```

    keep <- sample.int(nrow(dat), args$Subsample)
    dat <- dat[keep, ]
  }
  fit <- caret::train(Y ~ I(10*A) + W, ## a tweak
    data = dat,
    method = "kkn",
    verbose = FALSE,
    ...)
  fit$finalModel$fitted.values <- NULL
  ## nms <- names(fit$finalModel$data)
  ## for (ii in match(setdiff(nms, ".outcome"), nms)) {
  ##   fit$finalModel$data[[ii]] <- NULL
  ## }
  fit$trainingData <- NULL
  return(fit)
},
type_of_preds = "raw"
)
attr(kknn_algo, "ML") <- TRUE
kknn_grid <- expand.grid(kmax = 5, distance = 2, kernel = "gaussian")
control <- trainControl(method = "cv", number = 2,
  predictionBounds = c(0, 1),
  trim = TRUE,
  allowParallel = TRUE)

if(redo_fixed) {
  learned_features_fixed_sample_size <-
    learned_features_fixed_sample_size %>% # head(n = 100) %>%
    mutate(Qhat_d = map(obs, ~ estimate_Q(., algorithm = working_model_Q_one)),
      Qhat_e = map(obs, ~ estimate_Q(., algorithm = kknn_algo,
        trControl = control,
        tuneGrid = kknn_grid))) %>%

    mutate(blip_QW_d = map2(Qhat_d, obs,
      ~ compute_QhatAW(.y$Y, .y$A, .y$W, .x, blip = TRUE)),
      blip_QW_e = map2(Qhat_e, obs,
        ~ compute_QhatAW(.y$Y, .y$A, .y$W, .x, blip = TRUE)))
}

psi_hat_de <- learned_features_fixed_sample_size %>%
  unnest(blip_QW_d, blip_QW_e) %>%
  group_by(id) %>%
  summarize(est_d = mean(blip_QW_d),
    est_e = mean(blip_QW_e)) %>%
  mutate(std_d = sd(est_d),
    std_e = sd(est_e),
    clt_d = (est_d - psi_approx) / std_d,
    clt_e = (est_e - psi_approx) / std_e) %>%
  gather("key", "value", -id) %>%
  extract(key, c("what", "type"), "[^_+)-(de]") %>%
  spread(what, value)

(bias_de <- psi_hat_de %>% group_by(type) %>% summarize(bias = mean(clt)))

```

Figure 6: Write caption.

```
## # A tibble: 2 x 2
##   type    bias
##   <chr>  <dbl>
## 1 d      0.253
## 2 e      0.0368

fig <- ggplot() +
  geom_line(aes(x = x, y = y),
    data = tibble(x = seq(-3, 3, length.out = 1e3),
      y = dnorm(x)),
    linetype = 1, alpha = 0.5) +
  geom_density(aes(colt, fill = type, colour = type),
    psi_hat_de, alpha = 0.1) +
  geom_vline(aes(xintercept = bias, colour = type),
    bias_de, size = 1.5, alpha = 0.5)

fig +
  labs(y = "",
    x = expression(paste(sqrt(n/v[n]^{list(d, e)})*(psi[n]^{list(d, e)} - psi[0]))))
```

No that bad! Yet, we know that  $\sqrt{n}$  times bias is bound to increase with sample size. To see this, check out the next chunks of code.

```
sample_size <- c(4e3, 9e3)
block_size <- sum(sample_size)

label <- function(xx, sample_size = c(1e3, 2e3)) {
  by <- sum(sample_size)
  xx <- xx[seq_len((length(xx) %/% by) * by)] - 1
  prefix <- xx %/% by
  suffix <- findInterval(xx %/% by, cumsum(sample_size))
  paste(prefix + 1, suffix + 1, sep = "_")
}

if (redo_varying) {
  learned_features_varying_sample_size <- obs %>% as.tibble %>%
    head(n = (nrow(.) %/% block_size) * block_size) %>%
    mutate(block = label(1:nrow(.), sample_size)) %>%
```

```

    nest(-block, .key = "obs")
}

```

First, we cut the data set into independent sub-data sets of sample size  $n$  in  $\{4000, 9000\}$ . Second, we infer  $\psi_0$  as shown two chunks earlier. We thus obtain 76 independent realizations of each estimator derived on data sets of 2, increasing sample sizes.

```

if(redo_varying) {
  learned_features_varying_sample_size <-
    learned_features_varying_sample_size %>%
    mutate(Qhat_d = map(obs, ~ estimate_Q(., algorithm = working_model_Q_one)),
           Qhat_e = map(obs, ~ estimate_Q(., algorithm = kknn_algo,
                                         trControl = control,
                                         tuneGrid = kknn_grid))) %>%
    mutate(blip_QW_d = map2(Qhat_d, obs,
                           ~ compute_QhatAW(.y$Y, .y$A, .y$W, .x, blip = TRUE)),
           blip_QW_e = map2(Qhat_e, obs,
                           ~ compute_QhatAW(.y$Y, .y$A, .y$W, .x, blip = TRUE)))
}

root_n_bias <- learned_features_varying_sample_size %>%
  unnest(blip_QW_d, blip_QW_e) %>%
  group_by(block) %>%
  summarize(clt_d = sqrt(n()) * (mean(blip_QW_d) - psi_approx),
            clt_e = sqrt(n()) * (mean(blip_QW_e) - psi_approx)) %>%
  gather("key", "value", -block) %>%
  extract(key, c("what", "type"), "([~_]+)_([de])") %>%
  spread(what, value) %>%
  mutate(block = unlist(map(strsplit(block, "_"), ~.x[2])),
         sample_size = sample_size[as.integer(block)])

```

The tibble called `root_n_bias` reports root- $n$  times bias for all combinations of estimator and sample size. The next chunk of code presents visually our findings, see Figure 7. Note how we include the realizations of the estimators derived earlier and contained in `psi_hat_de` (thus breaking the independence between components of `root_n_bias`, a small price to pay in this context).

```

root_n_bias <- learned_features_fixed_sample_size %>%
  mutate(sample_size = B/iter) %>% # because *fixed* sample size
  unnest(blip_QW_d, blip_QW_e) %>%

## as soon as possible!

```

**2.19 One-step estimation.** Function `set_Qbar_Gbar` implements the change of the `Qbar` and `Gbar` attributes of `obs` (which are accessible only by oracles).

```

set_Qbar_Gbar <- function(obs, Qhat, Ghat) {
  attr(obs, "Qbar") <- function(newdata) {
    if (!is.data.frame(newdata)) {
      newdata <- as.data.frame(newdata)
    }
    predict(Qhat, newdata = newdata, type = Qhat$type_of_preds)
  }
  attr(obs, "Gbar") <- function(newdata) {
    if (!is.data.frame(newdata)) {
      newdata <- as.data.frame(newdata)
    }
    predict(Ghat, newdata = newdata, type = Ghat$type_of_preds)
  }
  return(obs)
}
eic_bar <- function(obs, Qbar, Gbar) {
}

```

First, we call function `set_Qbar_Gbar` to replace the true `Qbar` and `Gbar` attributes of `obs` by their estimated counterparts as stored in `learned_features_fixed_sample_size`. Second, we call function `eic` to compute the values of the estimated efficient influence at the observations in `obs`. Constructing the one-step estimators is then straightforward.

```

psi_hat_de_one_step <- learned_features_fixed_sample_size %>%
  mutate(obs_d = pmap(list(obs = obs, Qhat = Qhat_d, Ghat = Ghat),

```

Figure 7: Evolution of root- $n$  times bias versus sample size for two inference methodology of  $\psi_0$  based on the estimation of  $\bar{Q}_0$ . Big dots represent the average biases and vertical lines represent twice the standard error.

```

      set_Qbar_Gbar),
      obs_e = pmap(list(obs = obs, Qhat = Qhat_e, Ghat = Ghat),
        set_Qbar_Gbar)) %>%
mutate(eic_obs_d = map2(obs_d, blip_QW_d, ~ eic(as.data.frame(.x), mean(.y))),
      eic_obs_e = map2(obs_e, blip_QW_e, ~ eic(as.data.frame(.x), mean(.y)))) %>%
unnest(blip_QW_d, eic_obs_d,
      blip_QW_e, eic_obs_e) %>%
group_by(id) %>%
summarize(est_d = mean(blip_QW_d) + mean(eic_obs_d),
          std_d = sd(eic_obs_d),
          clt_d = sqrt(n()) * (est_d - psi_approx) / std_d,
          est_e = mean(blip_QW_e) + mean(eic_obs_e),
          std_e = sd(eic_obs_e),
          clt_e = sqrt(n()) * (est_e - psi_approx) / std_e) %>%
gather("key", "value", -id) %>%
extract(key, c("what", "type"), "([^-]+)_([de])") %>%
spread(what, value) %>%
mutate(type = paste0(type, "_one_step"))

(bias_de_one_step <- psi_hat_de_one_step %>%
  group_by(type) %>% summarize(bias = mean(clt)))

```

```

## # A tibble: 2 x 2
##   type      bias
##   <chr>     <dbl>
## 1 d_one_step -0.0208
## 2 e_one_step  0.00142

```

```

ggplot() +
  geom_line(aes(x = x, y = y),
    data = tibble(x = seq(-3, 3, length.out = 1e3),
      y = dnorm(x)),
    linetype = 1, alpha = 0.5) +
  geom_density(aes(clt, fill = type, colour = type),
    psi_hat_de_one_step, alpha = 0.1) +
  geom_vline(aes(xintercept = bias, colour = type),
    bias_de_one_step, size = 1.5, alpha = 0.5) +
  labs(y = "",
    x = expression(
      paste(sqrt(n/v[n]^{list(dos, eos)}) * (psi[n]^{list(dos, eos)} - psi[0]))))

```

It seems that the one-step correction is quite good (in particular, compare `bias_de` with `bias_de_one_step`):

```
bind_rows(bias_de, bias_de_one_step)
```

```

## # A tibble: 4 x 2
##   type      bias
##   <chr>     <dbl>
## 1 d         0.253
## 2 e         0.0368
## 3 d_one_step -0.0208
## 4 e_one_step  0.00142

```

What about the estimation of the asymptotic variance, and of the mean-square errors of the estimators?

Figure 8: Write caption.

```
psi_hat_de %>%
  full_join(psi_hat_de_one_step) %>% group_by(type) %>%
  summarize(sd = mean(std * ifelse(str_detect(type, "one_step"), 1, NA),
    se = sd(est) * sqrt(n()),
    mse = mean((est - psi_approx)^2) * n()))
```

```
## # A tibble: 4 x 2
##   type      sd
##   <chr>    <dbl>
## 1 d        NA
## 2 d_one_step 0.549
## 3 e        NA
## 4 e_one_step 0.483
```

The `sd` (*estimator* of the asymptotic standard deviation) and `se` (*empirical* standard deviation) entries for type `d_one_step` are very similar: this indicates that the inference of the asymptotic variance of the `d`-variant of the one-step estimator based on the influence function is accurate. *This comes as a surprise, since theory suggests that estimation should be conservative, that is, that the estimator should produce an upper bound to the actual asymptotic variance.* On the contrary, the influence function-based estimator of the asymptotic variance is clearly very conservative for type `e_one_step`. As for the mean square error, it is diminished by the one-step update for type `d` and enlarged for type `e`, the `d_one_step` estimator exhibiting the smallest mean square error.
